# A natural hybrid of Leuciscus cephalus macedonicus $\times$ Chalcalburnus chalcoides macedonicus (Pisces, Cyprinidae) from Lake Volvi (Macedonia, Greece) 

P. S. Economidis and A. I. Sinis<br>Department of Zoology, Faculty of Sciences, University of Thessaloniki, GR-54006 Thessaloniki, Greece

(Received 25 June 1987, Accepted 1 September 1987)

#### Abstract

A massive hybridization between Leuciscus cephalus macedonicus and Chalcalburnus chalcoides macedonicus has been recognized and studied by examining 67 specimens from Lake Volvi (Macedonia, Greece). The majority of meristic and other characters present an intermediate position in the hybrid (total hybrid index $V h=38.37$ ). Nevertheless, the best expression of intermediacy is shown most clearly by the numbers of anal fin soft rays, lateral line scales and gill rakers. and also by the height of the dorsal fin and the length of the base of anal fin. Of the examined hybrid specimens. $92.5 \%$ were females. It seems that hybridization takes place during the reproduction period in the main streams flowing into the lake under special conditions which hinder the migration of the majority of the population of $C$. chalcoides from the lake to the breeding sites. It is suggested that individuals of $C$. chalcoides, which manage to arrive in these sites, mate with $L$. cephalus, the normal inhabitant of the streams, thus producing the hybrid.

## I. INTRODUCTION

Hybridization is a widespread phenomenon in nature. In fishes, our knowledge is most advanced for the freshwater species, partly because hybrids are more frequent in fresh water than in the sea and because freshwater fish populations are better studied. It is also enhanced by the increasing interest in hybrids, and because the frequency of hybrids has considerably increased due to environmental changes. This is readily seen by comparing the number of publications concerning hybrids reported in the lists of Slastenenko (1957) and Schwartz (1972, 1981).

These lists do not report any hybrids of freshwater fishes in Greece. The only hybrid to have been reported in Greece is Barbus albanicus $\times$ Barbus graecus, described by Stephanidis (1939), based on a single specimen from the Acheloos river (Western Greece)*. The recognition of hybrids in a natural population is a reflection of the relatively good state of knowledge of the Eurasian fish fauna as well as of a more intensive scrutiny of unusual-looking fishes (Wheeler \& Easton, 1978). This ' relatively good state of our knowledge' of the freshwater fish fauna of Greece allowed us to recognize a massive hybridization between the endemic subspecies Leuciscus cephalus macedonicus Karaman, 1955 and Chalcalburnus chalcoides macedonicus Stephanidis, 1971 in Lake Volvi, as well as other hybrids which are now under study. Hybridization between Leuciscus cephalus and Chalcalburnus chalcoides and their subspecies seems to be rare or not so well studied, since it has been reported only a few times (in the Soviet Union, Berg, 1949; see also Slastenenko, 1957; Schwartz, 1972, 1981).

## II. MATERIALS AND METHODS

The hybrid was found in Lake Volvi, Macedonia (Fig. 1). Sampling was carried out from commercial catches. In two samples ( 21 September 1972 and 12 October 1972), 67 hybrid specimens (s.L. $157-208 \mathrm{~mm}$ ) were found among Chalcalburnus chalcoides macedonicus and Leuciscus cephalus macedonicus. These specimens are deposited in the Zoological Museum of the University of Thessaloniki (ZMUT) (no. VA-70 and no. VA-71). Additionally, eight specimens (s.L. 163-184 mm) from the same samples are deposited in the National Museum of Natural History in Paris (MNHN) (no. 1975-731 and no. 1975-744). Ten more specimens (s.L. 162-204 mm) were collected in Lake Volvi on 20 and 30 October 1984 (ZMUT no. VA-81). Samples of the putative parental species were also obtained from the same lake.

Thirty-nine major characters were examined. Vertebral counts included the four vertebrae of the Weberian complex but excluded the urostyle. The last branched (soft) ray of the dorsal and anal fins was counted as two. Morphometric characters were measured to 0.1 mm with calipers, and are expressed as a percentage of standard length or head length. The mean $(\bar{x})$, standard error ( $S x$ ), standard deviation $(s)$ and coefficient of variation (C.V.) were estimated. The hybrid index of Hubbs \& Kuronuma (1943) was estimated according to the formula

$$
V h=\frac{1}{m} \sum_{i=1}^{m}(x h i-\mu 1 i / \mu 2 i-\mu 1 i),
$$

where $x h i$ is the value of the character $i$ for the hybrid $h, \mu 1 i$ and $\mu 2 i$ are the means for the character $i$ in the parental populations 1 and 2, and $m$ is the number of characters (Smith, 1973). For each character, the hybrid index may have values between 0 and 100. Negative values or 0 correspond to Leuciscus cephalus macedonicus, and values of 100 or more to Chalcalburnus chalcoides macedonicus. The ideal expression of intermediacy for a hybrid is the value 50 , although index values between $30-70$ are considered intermediate (Ross \& Cavender, 1981).

Despite some disadvantages, the hybrid index provides a total impression of intermediacy, especially when allometry is avoided. The overall aim is to prove, through different ways, the real fact of hybridism, and towards this the hybrid index is undoubtedly of great importance. Some other qualitative morphological characters showing a remarkable intermediacy in the hybrid were also examined. The variability of a number of characters, and their intermediacy in the hybrid, are presented according to the method proposed by Hubbs \& Perlmutter (1942) and Hubbs \& Hubbs (1953). Examination of the gonads for sex determination was made macroscopically.

## III. RESULTS

The hybrid is known to the fishermen under the common name ' lakkopsaro', meaning ‘streamfish'. This name also characterizes Leuciscus cephalus macedonicus in the area, which resembles the hybrid (Fig. 2). However, examination indicates that the hybrid is distinguished by a thinner and higher body, and an anal fin with a straight margin and $10-11$ branched rays ( 13 in one specimen only). On the other hand, in the shape of the snout and head, the hybrid resembles $C$. chalcoides. There are other characters which separate the hybrid from the two parental species and show it to be intermediate between them: of the 31 meristic characters and proportions of the body examined, 21 ( $68 \%$ ) appear to have an intermediate expression in the hybrid (Tables I-III).

## MERISTIC CHARACTERS

Five of the eight meristic characters are intermediate, one (type of pharyngeal teeth) is invariable, and two (rays of pectoral fin and vertebrae) show a greater average value in the hybrid than in the two parental species (Table I). The hybrid shows a greater range of values of branched rays in the pectoral fins. The number of vertebrae is clearly greater in the hybrid, both the average and extreme values. The other meristic characters have an intermediate value in the hybrid. Four of these (branched rays of anal and of ventral fins, gill rakers, and scales of the lateral line) are closer to $L$. cephalus (average hybrid index $V h=30 \cdot 25$ ) and only one (branched rays of dorsal fin) is closer to C. chalcoides ( $V h=86$ ). The number of branched rays of the anal fin [Fig. 3(b)], the number of scales in the lateral line [Fig. $3(\mathrm{~d})$ ] and the number of gill rakers [Fig. 3(e)] show most clearly the intermediacy in the hybrid. In this last character, it is important to note that there is no overlap in extreme values, and the range of values of the hybrid is small relative to $C$. chalcoides. The same stability in values and their range is also observed in the branched rays of the anal fin [Fig. 3(b)] where the only divergence was due to a single specimen of the hybrid with 13 rays. There is some overlap in the extreme values of the number of scales of the lateral line [Fig. 3(d)] in the hybrid. The values are more stable in $L$. cephalus ( 5 scales), relatively stable in the hybrid ( 10 scales) and more variable in C. chalcoides ( 14 scales).

Fig. 3. Meristic (a)-(e) and morphometric (f)-(t) characters showing hybrid (H) intermediacy between parental species (L.c., Leuciscus cephalus macedonicus; C.c., Chalcalburnus chalcoides macedonicus). Range (horizontal line), mean (vertical line), one s.e. (black bar) and one s.D. (clear bar) on each side of the mean. Horizontal axis units are counted numbers for meristic characters and percentages for morphometric characters. Values are based on data in Tables 1-III.

## MORPHOMETRIC CHARACTERS

The hybrid has a medium-sized body, greater than the two parental species, at least of those examined (Table II). This applies especially to C. chalcoides, as this species rarely reaches a total length of 250 mm . However, L. cephalus reaches a greater size in other freshwater ecosystems of Greece, but in Lake Volvi fishing mortality probably causes a lack of larger specimens. Consequently, we cannot prove that the hybrid shows heterosis. However, the fact that the specimens of the hybrid and those of the two parental species are almost of the same size indicates that the other proportions of the body are apparently comparable, without any difficulties from allometry. Therefore, Table II shows that the hybrid has greater body depth and slightly greater caudal peduncle length than $L$. cephalus, and clearly greater than C. chalcoides, and a small eye, preorbital distance and postorbital distance. These two last characters show a coefficient of variation (C.V.) almost twice as large as those of the two parental species, indicating greater variability. The other four proportions of the body (depth of caudal peduncle, head length, eye diameter and interorbital distance) have intermediate values in the hybrid. Of these characters, only head length is closer to C. chalcoides ( $V h=81$ ), the other three being closer to $L$. cephalus. The total hybrid index for these nine proportions of the body presents an intermediate value, $V h=39 \cdot 11$ (Tables II, V). However, it is evident that this group of characters does not express the intermediacy very well, because five of them ( $55.6 \%$ ) are with $V h=0$ or 100.

The 12 characters which determine the position and size of fins (Table III) are mostly intermediate, with average $V h=35 \cdot 67$. The only exception is the length of the ventral fins, which are smaller in the hybrid. Nine characters were closer to $L$. cephalus (average $V h=21 \cdot 67$ ) whilst only length of base of dorsal fin and depth of anal fin were closer to C. chalcoides ( $V h=66 \cdot 5$ ).

The best expression of intermediacy is the height of the dorsal fin [Fig. 3(k)] ( $V h=40$ ) and length of the base of the anal fin [Fig. 3(n)] $(V h=38)$. In the latter character there is almost no overlap in the ranges of values, as is also the case with the numbers of the branched rays of the anal fin [Table I, Fig. 3(b)].

## OTHER CHARACTERS

Many qualitative characters of the hybrid show a remarkable intermediacy (Table IV): the colour pattern of the body and fins, and the pigmentation of the peritoneum, are in intermediate positions, as are the free margin of the anal fin and position of the dorsal fin. The form of the snout and the orientation of the mouth resemble C. chalcoides, whilst the form of the keel resembles $L$. cephalus.

## COEFFICIENT OF VARIATION AND HYBRID INDEX

The hybrid shows a mean coefficient of variation of 4.99 (Table V ), not significantly different from those of the parental species. In the morphometric characters, the coefficient of variation of the hybrid is between that of the parental species, whereas for the meristic characters it is clearly smaller.

The total hybrid index is $V h=38.37$ (Table V). The closest to the ideal state for hybridization appears in the average index of the meristic characters ( $V h=41 \cdot 22$ ), but the index for the other characters is also close to intermediacy. However, the average hybrid index, in all cases, is smaller than 50 , which indicates that the hybrid is more similar to L. cephalus than to C. chalcoides.
Table IV. Some significant qualitative characters showing an intermediacy in hybrid

| Character | L.c. macedonicus | Hybrid | C.c. macedonicus |
| :---: | :---: | :---: | :---: |
| Free margin of anal fin | Convex | Straight | Concave |
| Peritoneum | Homogeneous, dark brown | Spotted, light brown | Spotted, light |
| Mouth | Terminal | Sub-dorsal | Dorsal |
| Snout (dorsal view) | Rounded | Intermediate | Angular |
| Abdominal keel | Absent | Small, often existing in front of the anus | Well developed |
| Pigmentation in anal fin | Dark in margin | Sparse | Without pigmentation |
| Pigmentation in scales at the sides of the body | Peripheric | More or less periferic or absent | All over the surface or absent |
| Pigmentation in cheeks | Well visible | Scarcely visible | Scarce or absent |
| Distance between insertions of dorsal and anal fins | One-third of the dorsal base | One-half of the dorsal base | Three-quarters of the dorsal base |

Table V. Coefficients of variation and hybrid index of Hubbs \& Kuronuma

*Calculation for all characters from 0 to 100.
SEX RATIO
In the hybrid, the dominance of the females over males is significant: of the 67 specimens of the hybrid, $62(92.5 \%)$ were females, so the female:male ratio was $12 \cdot 4: 1$. This great divergence from $1: 1$ indicates some abnormality, and provides additional proof of the identity of the hybrid and an indication of its possible sterility.

## IV. DISCUSSION

Fish hybridization is favoured by genetic factors such as compatibility of genes (Dubois, 1981), simple reproductive behaviour (Pépin et al., 1970), and ecological factors such as coincidence (in space and time) of reproduction (Hubbs, 1955). In cyprinids, these conditions are met to a significant degree, so that the hybrids are not very rare. This fact sometimes makes the criteria of separation of typical genera within this group doubtful (Pepin et al., 1970). However, in nature, hybridization is usually not a very extensive or massive phenomenon. This preserves the autonomy of natural fish populations and justifies the maintenance of traditional nomenclature. Under natural conditions genetic incompatibility produces various blocks affecting the viability and fertility of hybrids (Hubbs, 1961) so that hybrids are often degenerate and parental populations can be maintained.

Hybridization can be increased in some cases, such as by the introduction of a species into an aquatic system where very closely related species live (Daget \& Moreau, 1981), or where the environment is changed either through natural causes or by man (Hubbs, 1955). We believe that the massive hybridization between Leuciscus cephalus macedonicus and Chalcalburnus chalcoides macedonicus in the Lake Volvi system may be attributed to the latter.

The recognition of this hybrid was difficult at first; because a large number of adults were found, they gave the impression of an undescribed Leuciscus species. Besides the 67 individuals caught in two temporally close samples, the hybrid was fished for a long time before and after, so that its population in the lake was large.

An earlier faunistic study (Economidis \& Sinis, 1982) left open the question of whether it was a new Leuciscus species or a hybrid. Even after the analysis of characters showed significant intermediacy (in comparison with the supposed parental species) (Economidis \& Sinis, 1986), the problem of the presence of a large number of individuals raised the question: was such a massive hybridization possible in the balanced lake system of Volvi?

Leuciscus cephalus and C. chalcoides may coexist during the breeding season in streams flowing into the lake, especially those of Pasarouda and Melissourgos. L. cephalus is a rheophilous species with an important population remaining almost continuously in these streams, where they also breed. Chalcalburnus chalcoides is more limnophilous, and forms an important exploited population in Lake Volvi. In the past, this species migrated massively to breed in the streams. In the area, there are traditions and ancient texts which refer to the great size and density of migrating shoals. Athenaeus (second-third century A.D.) wrote: " Round Apollonia, in the Chalcidic peninsula, flow two rivers, the Sandy and the Olynthiac. Both empty into Lake Bolbe [=Volvi]. On the Olynthiac is a monument to Olynthus, the son of Heracles and Bolbe. In the months Anthesterion and Elaphebolion, so say the inhabitants, Bolbe sends the broiler to Olynthus, and at this time a limitless quantity of fish go up from the lake into the Olynthiac river. Now it is a stream so shallow that it hardly covers the ankle, nevertheless such a quantity of fish comes that all the inhabitants round about can put up preserved fish sufficient for their needs." Nowadays, this migration tends to be interrupted, due to increased agriculture and urbanization resulting in reduction of the water volume of the streams. The population of L. cephalus still remains in the streams, whereas migration of $C$. chalcoides from the lake is hindered by small irrigation dams along the streams. Migration of C. chalcoides is possible only during years with high rainfall in spring (mostly April). Thus, reproduction of this species sometimes coincides in time and space with that of L. cephalus, producing conditions for massive hybridization. Breeding sites are of small area with clear running shallow water and gravel bottom, because both species are lithophilous (Balon, 1975). Consequently, gamete-mixing of the two species occurs, as happens with other species breeding in rivers (Hubbs, 1955; Ross \& Cavender, 1981). It seems that single individuals of $C$. chalcoides mixing with the spawning $L$. cephalus play an important role in the massive hybridization. This is similar to cases of hybridization reported in southern U.S.A. (Hubbs, 1955), Italy (Bianco, 1982), Portugal (Collares-Pereira \& Coelho, 1983) and even those where special breeding conditions are required (Holčik, 1977).

There are strong indications that the hybrids are produced by female $L$. cephalus and male C. chalcoides. The hybrids mostly resemble L. cephalus, the total hybrid index, $V h=38 \cdot 37$ (Table V), being closer to L. cephalus. The females of $L$. cephalus are resident in the stream and better adapted to the environment so that solitary males of $C$. chalcoides preceeding the females in ascending streams meet females of L. cephalus at the breeding areas.

Berg (1949) has also described hybridization between L. cephalus and C. chalcoides based on intermediate characters, but these were not reported in detail. Howes (1981) rejected that example: " as enumerated, these characters could well describe a populational variant of one of the presumed parental species". In Lake Volvi, however, it is clear that this hybridization exists. Otherwise, it is difficult to
explain the stable occurrence, in a large sample of 67 fish, of 10-13 branched rays in the anal fin, while L.cephalus and C. chalcoides are known in the same lake system to have almost invariably $7-8$ and $14-17$ rays, respectively. Thus, the hybrid coexists with typical forms of the two parental species and cannot simply be rejected as a variant of either.

We thank Mr Alwyne Wheeler, British Museum (Natural History) for making critical comments on the manuscript, Dr A. Hailey (London University) for useful remarks and linguistic review of the text, and Mrs Joëlle Defaÿ (Nice Museum) for the drawing of the hybrid (Fig. 2).
